## Assignment #7

## Due on Monday, April 6, 2020

**Read** Section 4.1.2 on *Discrete Random Variables* in the class lecture notes at http://pages.pomona.edu/~ajr04747/.

**Read** Section 4.1.3 on *The Binomial Distribution* in the class lecture notes at http://pages.pomona.edu/~ajr04747/.

**Read** Section 4.1.4 on *Expected Value* in the class lecture notes at http://pages.pomona.edu/~ajr04747/.

 $\mathbf{Do}$  the following problems

1. Given a discrete random variable X with a finite number of possible values

$$x_1, x_2, x_3, \ldots, x_N,$$

the expected value of X is defined to be the sum  $E(X) = \sum_{i=1}^{N} x_i P[X = x_i].$ 

Use this formula to compute the expected value of the numbers appearing on the top face of a fair die. Explain the meaning of this number.

- 2. Consider the following random experiment: Assume you have a fair die and you toss it until you get a six on the top face, and then you stop. Let X denote the number of tosses you make until you stop.
  - (a) Explain why X is a discrete random variable. What are the possible value for X?
  - (b) For each value x of X, compute P[X = x]; this is called the *probability* mass function, or pmf, of the random variable X.
- 3. Given a discrete random variable X with an infinite number of possible values

$$x_1, x_2, x_3, \ldots$$

the expected value of X is defined to be the infinite series

$$E(X) = \sum_{i=1}^{\infty} x_i P[X = x_i].$$

Use this formula to compute the expected value random variable X of the previous problem; that is, X is the number of times you need to toss a fair die until you get a six on the top face.

4. Let M(t) denote number of bacteria in a colony of initial size  $N_o$  which develop mutations in the time interval [0, t]. It was shown in the lectures that if there are no mutations at time t = 0, and if M(t) follows the assumptions of a Poisson process, then the probability of no mutations in the time interval [0, t] is given by

$$P_0(t) = P[M(t) = 0] = e^{-\lambda t}$$

where  $\lambda > 0$  is the average number of mutations per unit time, or the *mutation* rate.

Let T > 0 denote the time at which the first mutation occurs.

- (a) Explain why T is a random variable. Observe that it is a *continuous* random variable.
- (b) For any t > 0, explain why the statement

$$P[T > t] = P[M(t) = 0]$$

is true, and use it to compute

$$F(t) = P[T \le t].$$

The function F(t), usually denoted by  $F_T(t)$ , is called the *cumulative dis*tribution function, or cdf, of the random variable T.

(c) Compute the derivative f(t) = F'(t) of the cdf F obtained in the previous part.

The function f(t), usually denoted by  $f_T(t)$ , is called the *probability density* function, or pdf, of the random variable T.

5. Given a continuous random variable X with pdf  $f_X$ , the *expected value* of X is defined to be

$$E(X) = \int_{-\infty}^{\infty} x f_X(x) dx.$$

Use this formula to compute the expected value of the T, where T is the random variable defined in the previous problem; that is, T > 0 is he time at which the first mutation occurs for a bacterial colony exposed to a virus at time t = 0, assuming that there are no mutations at that time. How does this value relate to the average mutation rate  $\lambda$ ?
